PERCUTANEOUS SCREW REMOVAL IN SLIPPED UPPER FEMORAL EPIPHYSIS

MARTIN A. GRUBER, KEITH D. STARKWEATHER, WILLIAM A. HEALY III, SUSAN HARALABATOS
From the State University of New York, Stony Brook, USA

Several authors have reported complications from screw removal after treatment of slipped upper femoral epiphysis by single screw fixation, and have attributed these to poor screw design. We have developed a simple and reliable method of screw removal which uses a cannulated 8.0 mm end-threaded cancellous screw (Smith & Nephew Richards Medical, Memphis, Tennessee) and a specially designed cannulated trephine.

The method has been successful, with minimal complications, and a limited surgical exposure.

Slipped upper femoral epiphysis (SUFE) is the most common hip disorder in adolescents (Tachdjian 1990). Left untreated or neglected, slip tends to increase, which exacerbates the deformity and adversely affects the long-term outcome (Hall 1957). The goal of surgical treatment is to prevent further slipping and to induce physeal closure (Lehman et al 1984; Stambough et al 1986; Lehman 1988). Treatment has evolved into standard fixation by a single screw (Stambough et al 1986; Crawford 1988; Ward et al 1992).

Several authors have reported complications, however, should the screw need to be removed after physeal closure (Swiontkowski 1983; Greenough, Bromage and Jackson 1985; Larsson and Friberg 1987; Crandall, Gabriel and Akbarnia 1992; Warner, Bramley and Kay 1994). One of us (MAG) therefore developed a new and reliable method of removal, with few complications. We report our preliminary experience with this technique which is easy to learn and minimally invasive.

PATIENTS AND METHODS

We used a cannulated 8.0 mm end-threaded cancellous screw (Smith & Nephew Richards Medical, Memphis, Tennessee) which is readily available. It has a prominent head which is the male portion of a hexagonal socket (Fig. 1). This increases the contact area between the screwdriver and screw head, and reduces the risk of stripping the screw head during removal. The contact area in this screw head is 82.0 mm$^2$ compared with approximately 40 mm$^2$ in female hexagonal screw heads. The screwdriver is the female portion of the socket. This arrangement tends to clean soft tissue from the screw head as the screwdriver is locked into place. The triflanged screw tip is self-tapping and has reverse cutting flutes for easier removal. The thick core of the screw helps to protect against shear failure.

Screw removal is performed with the patient on a fracture table, using biplane fluoroscopy to pass a guide pin percutaneously into the cannula of the screw. If the screw head is overgrown by bone, a drill is used to advance the sharp end-threaded guide pin through the bone into the screw cannula. Once the guide is in place, a 1.5 cm longitudinal incision is centred on the pin and a cannulated soft-tissue dilator is inserted over the pin to expand the skin and subcutaneous tissues.

A cannulated reamer is then passed through the soft-tissue protector and used to ream away any bone and fibrous tissue that may have overgrown the screw head. The reamer is removed, and a cannulated trephine is advanced by hand along the guide pin until it sits on the screw head (Figs 2 to 4). This cleans bone and fibrous tissue away from the hexagonal head, and this is complete when the trephine reaches a flared stop at the base of the screw head.

The trephine is then removed and the screwdriver is advanced along the guide pin until it sits completely on the screw head, as confirmed by fluoroscopy. The guide pin is removed, and a locking pin is inserted through the screwdriver to lock the screw and screwdriver together. The screw is then removed.

The incision is closed with a subcutaneous absorbable suture and sterile adhesive strips. An elastic bandage spica dressing is retained for 24 hours, but patients are allowed to...
bear full weight and leave hospital on the same day. Full activities are permitted after six weeks.

RESULTS

We reviewed the records of all patients with SUFE who had had percutaneous removal of 8.0 mm cannulated screws between June 1993 and January 1995, excluding those who had had other procedures at the same time. Ten patients (16 hips) met the criteria; nine were male and six had bilateral screws. The mean age at the time of fixation had been 13 years 1 month (11 years 11 months to 14 years 10 months); the screws were removed at a mean of 17.1 months after insertion (9 to 34).

Four unilateral screw removals took a mean operating time of 30.5 minutes (15 to 50) and six bilateral procedures
occupied a mean operating time of 60 minutes (35 to 95). All patients were discharged within 24 hours.

There were no cases of infection, haematoma, fracture, metal failure, or neurovascular complications.

DISCUSSION

The treatment of SUFE by single screw fixation is common but the type of screw and the ability to remove it safely and reliably are still under discussion. Several authors have reported complications including bent and broken screws, fractures, secondary osteomyelitis, inability to remove screws, prolonged operating time, and delayed recovery (Greenough et al 1985; Larsson and Friberg 1987; Crandall et al 1992; Warner et al 1994). These problems have led some authors to advise against screw removal unless it is absolutely necessary.

We have shown that the use of an 8.0 mm cannulated screw with a male hexagonal screw head facilitates removal, using a cannulated trephine through a limited surgical approach. This technique has allowed consistently uncomplicated screw removal, with minimal operating time, surgical exposure, and hospital stay.
