We treated 35 patients with primary malignant tumours of the periacetabular area by resection and prosthetic reconstruction of the defect. At a mean follow-up of 84 months, 15 patients (43%) were free from disease. The most common complications were deep infection (26%), local recurrence (24%) and recurrent dislocation of the hip (17%). The surviving patients achieved an average of 70% of their premorbid function.

This method of reconstruction has a high morbidity and should be performed only at specialist centres, but the functional and oncological outcomes are satisfactory.

Received 25 March 1996; Accepted after revision 12 May 1997

About 15% of all primary malignant bone tumours involve the pelvis. Advances in the control of systemic and local disease by effective chemotherapy have improved survival and allowed more limb-preserving surgery. The overall survival of patients after limb-salvage surgery or amputation is similar when adequate excision margins are achieved. The anatomy and the usually large size of pelvic tumours make adequate excision with preservation of the limb a daunting challenge. Limb salvage for malignant pelvic tumours can preserve more function and avoid some of the social and psychological costs associated with hindquarter amputation.

Early surgical attempts to excise pelvic tumours were made by Enneking and Steel, and were associated with high morbidity and mortality. Recent developments in imaging, anaesthesia, blood transfusion and surgery have stimulated development of improved techniques and enlarged the indications for limb preservation in patients with malignant pelvic bone tumours.

Adequate excision of malignant periacetabular tumours often requires complete excision of the acetabulum and partial or complete excision of the pubis and ischium as Enneking and Dunham type-II or type II-III pelvic excisions (Fig. 1). Extra-articular excision of the hip within its enveloping capsule may be needed, leaving a flail hip or pseudarthrosis, but arthrodesis of the femur to the remaining ilium, pubis, ischium or sacrum can provide improved stability. Flail hip, pseudarthrosis and arthrodesis all leave considerable limb shortening, poor function, pelvic tilt and impaired gait, and may lead to back pain.

The emphasis is now on anatomical reconstruction by biological or mechanical means. Biological reconstruction uses allografts or reimplantation of excised bone after sterilisation by autoclaving. Allografts may be combined with a prosthesis as a composite. We have used mechanical reconstruction of the defect with custom-made prosthetic implants over the last 25 years. These provide maintenance of limb length and early restoration of function.

We now evaluate our experience, the surgical and technical complications, and the functional outcome of prosthetic reconstruction of the hemipelvis and hip after the excision of malignant periacetabular tumours.

PATIENTS AND METHODS

Between 1971 and 1994, a total of 35 patients had excision of periacetabular tumours for malignant bone tumours at either the London or the Birmingham Bone Tumour Treata
ment Centres. We reviewed all the patients from both centres retrospectively. The indications for excision included chondrosarcoma in 14 patients, histological grade 1 in four and grades 2 or 3 in ten, Ewing’s sarcoma in eight, osteosarcoma in four, malignant fibrous histiocytoma (MFH) in four, solitary metastatic renal-cell carcinoma in three, plasmacytoma in one and angiosarcoma in one. At diagnosis, staging studies included blood and serum biochemistry, whole body bone scintigraphy, chest radiography, chest CT with plain radiography and CT or MRI of the pelvis. All 35 patients, other than the three with metastatic renal-cell carcinoma, had stage-IIB tumours on the Musculoskeletal Tumor Society grading system.

We obtained clinical data from the hospital databases, case notes and imaging examinations. The average age of the patients was 32 years (13 to 66), the mean follow-up was 49 months (12 to 312) and 20 of the 35 patients were female. All the patients with Ewing’s sarcoma, osteosarcoma, MFH and angiosarcoma had chemotherapy according to the protocols current at the time. The function of all 21 surviving patients was assessed using the Musculoskeletal Tumor Society system.

No patient was lost to follow-up.

After staging studies, tissue diagnoses were obtained by needle or open biopsy using incisions or approaches along the proposed skin incision for the excision. Clearance biopsies were taken when necessary to confirm absence of tumour at a proposed site of bone transection from the ilium above the tumour. The need for such clearance biopsies has reduced with improved imaging methods, but may still help in confirming the proposed level of transection for the design of the prosthesis and at the operation.

All our patients were catheterised to maintain an empty bladder; some had bowel preparation with an enema. All the operations were performed under general anaesthesia with the patient in the lateral position, and were covered by prophylactic broad-spectrum antibiotics including metronidazole.

All patients had preoperative counselling about the need to eradicate the tumour and were warned that it might be impossible technically to preserve the limb; they all consented to amputation in such conditions.

Technique of operation. The operative details varied from patient to patient, but there were common features. We used part or all of an Ollier and an ilioinguinoperineal approach. The abdominal muscles were detached from the ilium and the pubis to allow examination of the pelvic cavity and mobilisation of the external iliac vessels, femoral nerve and psoas tendon. The muscles arising from the ilium were detached as far posteriorly as the sciatic notch to allow dislocation of the hip, division of the femoral neck and identification of the resection level in the ilium. Muscle attachments to the pubis and ischium were divided as required. The sciatic nerve and its branches were identified and preserved as were the internal iliac artery and its branches where possible.

The ilium was divided at the predetermined level and the portion of the pelvis containing the intact tumour was removed. Early in the series we routinely used a two-stage procedure (see below) and then developed a one-stage operation. In this custom-made endoprostheses were grouped to the ilium with bone cement and a total hip replacement was completed at the first operation. After replacement the muscles were reattached as far as possible and the wound closed over a suction drain.

The ilium was divided at the predetermined level and the portion of the pelvis containing the intact tumour was removed. Early in the series we routinely used a two-stage procedure (see below) and then developed a one-stage operation. In this custom-made endoprostheses were grouped to the ilium with bone cement and a total hip replacement was completed at the first operation. After replacement the muscles were reattached as far as possible and the wound closed over a suction drain.

After operation, patients rested in bed for an average of two weeks before being allowed to mobilise partially weight-bearing on crutches. At about six weeks, they started intensive physiotherapy to develop the hip and thigh muscles.
In the whole series 17 patients had two-stage procedures and 18 had a single operation for resection and replacement.

**Two-stage procedure.** At the first stage, the tumour was excised together with the biopsy track and femoral head and a cast was made of the cut iliac surface. A temporary acrylic resin construct and a conventional cemented femoral component were inserted (Fig. 2). The patient was placed in a hip spica cast and mobilised while the definitive prosthesis was manufactured.

The hemipelvic prosthesis was then custom-made from titanium, using the cast of the iliac surface and the resected specimen as templates for size, shape and orientation (Fig. 3). The second operation was usually about six weeks after the resection. The superior surface of the endoprosthesis was made to fit the cut surface of the ilium accurately and enclose it in a rim extension. The acetabular cavity of the prosthesis included two pins long enough to engage the full depth of the remaining ilium anteriorly and posteriorly. The upper surface of the endoprosthesis was grouted to the ilium with acrylic resin, the two pins were passed into the ilium and the acetabular polyethylene cup was grouted into the acetabular cavity with acrylic resin, which also served to lock the pins in position.

**One-stage procedure.** We now have the advantage of three-dimensional reconstructions of the pelvis from radiographs and CT scans. This allows the level of transection of the ilium to be determined before the operation, and prostheses can be manufactured before the resection. We use conventional Stanmore femoral prostheses with 32 mm heads as the femoral replacements.

**RESULTS**

At the time of review, 15 patients (43%) were alive and free from local or metastatic disease at a mean follow-up of 84 months (12 to 312). Six (17%) were alive with metastatic disease at a mean follow-up of 26 months (22 to 32). Twelve (34%) had died from metastatic disease and two...
Neither patient shows progression of the subsidence or tilt at four and 16 years after they were first observed. One young patient had aseptic loosening of the femoral prosthesis, requiring revision at five years.

**Back pain.** The incidence of significant back pain was low, with one case of sacroiliac pain, for which fusion of the sacroiliac joint has been advised.

**Incisional hernia.** One patient had an incisional hernia in the inguinal region after resection, which was successfully repaired using polyethylene mesh.

**Further operations.** A total of 14 patients (40%) required one or more additional procedures, for infection, gangrene, wear of the acetabular component, local recurrence, secondary haemorrhage, dislocation or loosening of the femoral component.

**Function.** We assessed function in the 13 patients with pelvic endoprostheses who were free from local or bony metastatic disease. We used the Musculoskeletal Tumor Society system which assesses pain, functional limitation, walking distance, use of support, emotional acceptance and gait. Each of these six variables was assessed on a five-point scale, giving a maximum score of 30 points, which we recorded as 100%. The average score was 70% (50 to 90) (Table II).

Our numbers are small and we found no difference between patients treated by one-stage or by two-stage procedures.

**DISCUSSION**

Limb preservation after the resection of malignant periacetabular tumours is technically difficult with many surgical complications despite advances in anaesthesia and imaging, and the improved surgical expertise provided by supra-regional treatment centres for bone tumours.

Our review of all such patients treated at the two main treatment centres for bone tumours in the UK shows surgical complications in 60%, with 40% requiring one or more operations for these. Similar complication rates of about 67% have been reported by Capanna et al and Rechl et al after the excision of pelvic tumours. Most of the complications result from the surgery involved in the excision of the tumour rather than from the method of reconstruction.

The complication rate after excision of pelvic tumours is marginally greater than that after hindquarter amputation. A previous report from one of our centres by Carter et al found a complication rate of 41% after hindquarter amputation with perioperative death in 9%. The types of complications after hindquarter amputations were similar to those after tumour excision and prosthetic reconstruction, including wound infection and necrosis, urinary fistula and infection, tumour embolism, renal failure and myocardial infarction, but there were no perioperative deaths after excision and prosthetic reconstruction.

Function after reconstruction by custom-made hemipelvic prostheses was satisfactory in most patients, reaching
Radiographs of our first patient on whom prosthetic replacement of the hemipelvis was performed 26 years ago.

Figure 4a – A tomograph showing a grade-I chondrosarcoma of the acetabulum (arrow).

Figure 4b – After two-stage excision and prosthetic reconstruction.

Figure 4c – Subsidence and varus tilt of the pelvic prosthesis occurred ten years after reconstruction, but did not progress. The patient is active and mobile, using one walking stick only for long outdoor walks.

</table>
an average of 70% of normal. The main muscle groups around the hip are usually preserved, since the abductors retain their proximal attachment to the remaining ilium, and psoas is usually preserved unless the proximal femur is also replaced. We believe that preservation of the sciatic nerve is essential for adequate function. If removal of the glutal vessels and nerves is necessary to resect the tumour, then limb preservation is contraindicated because there would be no abductor function.

The most important complications were local recurrence (23%) and infection (26%). The rate of local recurrence is similar to that in patients treated by hindquarter amputation in one of our centres. Other authors have also reported little difference in surgical morbidity and local recurrence rate between patients treated by hindquarter amputation or pelvic resection. Local recurrence can be treated by repeated local excision or by secondary hindquarter amputation. About 50% of patients who develop deep infection can be treated satisfactorily by debridement and antibiotics or by two-stage revision. We found that 40% of such infections were due to anaerobic organisms, which emphasises the need to use metronidazole for the initial antibiotic prophylaxis and to treat established infections.

There was recurrent dislocation of the hip in 17%, usually due to poor muscle function. The recommended treatment is closed reduction and intensive physiotherapy. In our series, one dislocation was secondary to wear of the polyethylene component which was controlled by changing the cup. Thrombosis of the femoral artery, presumably secondary to local trauma, has very serious consequences, which emphasises the importance of careful observation of the limb pulses.

When the iliac resection involves the sacroiliac joint, secondary degenerative changes may follow. To avoid this we have used a ‘step’ osteotomy which allows a more proximal division of the lateral ilium. We have used dual fixation of the pelvic prosthesis to both ilium and pubis but pubic fixation may be inadequate and loosening often develops. Our experience indicates that it is not necessary to close the pelvic ring.

Two of our patients developed a varus tilt of the pelvic prosthesis at six and ten years, respectively, after reconstruction; one of them had a secondary palsy of the sciatic nerve, which allowed a more proximal division of the lateral ilium. The complications of arthroplasty include limb shortening, abnormal gait, and back pain; only 40% have a satisfactory functional outcome.

Hemipelvic allografts carry an increased risk of infection, nonunion, fracture and protrusio acetabuli. The use of sterilised autografts is gaining popularity, but there is no evidence that they behave differently from allografts of the same size, although they should provide a better ‘fit’.

We consider that our method can achieve adequate excision and provide satisfactory reconstruction and function. The first patient in the series which we report continues to be active and mobile; at 26 years’ follow-up she achieved a 70% score for functional capability.

**Conclusions.** Prosthetic reconstruction of the hemipelvis after tumour excision is worthwhile in carefully selected patients. It is technically demanding; both patients and surgeons must be aware of the high incidence of complications. The multidisciplinary skills and experience required, and the need for careful follow-up and rehabilitation mean that patients who may require such management should be assessed and treated only in a specialist centre for orthopaedic oncology.
