Giant-cell tumour of the tendon sheath, also called pigmented villonodular synovitis, is a benign tumour with a high incidence of recurrence. We have tried to identify risk factors for recurrence. Of the 48 patients included in the study, 14 received radiotherapy after surgery. Only two (4%) had a recurrence. This compares favourably with previously reported incidences of between 25% and 45%.

Radiotherapy has been recommended to prevent recurrence after excision. We carried out a prospective study to assess the effectiveness of prophylactic radiotherapy in the postoperative period in selected cases to prevent recurrence.

Patients and Methods

Between 1986 and 1997 we treated 48 patients with giant-cell tumour of the tendon sheath of the hand. There were 30 women and 18 men with a mean age of 34.6 years (11 to 58). The mean duration of symptoms was 30 months (4 months to 8 years). Gradually progressive swelling was the only symptom; no patient complained of pain. A preoperative diagnosis of a giant-cell tumour of the tendon sheath was made in 42 patients. No patient had multiple lesions. The distribution of the lesions in the hand is shown in Table I. In six patients the lesions were on the dorsal aspect (Fig. 1), while in 31 the swelling was on the palmar aspect. In the other 11 patients the lesions were almost circumferential. Most were 3 to 4 cm in diameter and were firm, fibrous, lobulated and partially circumscribed by a fibrous capsule which was lacking in places. The cut surface of the tumour was grey-white mottled with pink, brown or yellow. Although meticulous surgical excision was attempted in all patients, in six it was considered to be incomplete.

Results

All the 48 lesions fitted the classical histological description of pigmented villonodular tenosynovitis (Fig. 2). Histological examination showed that the tumour was composed of a single set, or groups, of rounded or polygonal cells with round nuclei and faintly eosinophilic cytoplasm interspersed among giant cells. Foci of xanthomatous changes were seen. Granules of haemosiderin were present in the cytoplasm of the stromal cells, especially the foam cells. The giant cells were irregularly distributed and had a deeply eosinophilic cytoplasm with a variable number of nuclei ranging from four to 40. Mitotic figures, seen in eight cases, varied in number (2 to 6 per 10 high-power fields). There were no atypical mitoses. Neither bone, cartilage, calcification, cartilage debris or necrosis was seen. Plain radiographs showed soft-tissue swelling in 42 patients (Fig. 3). No bone erosion was seen.

Table I. The distribution of giant-cell tumour of the tendon sheath in the 48 patients
After operation, 14 patients, who had either mitotic figures or possible incomplete excision, were treated with local irradiation at 20Gy in divided doses (2Gy surface dose daily at 200kV). Patients in both the irradiated and non-irradiated groups were followed up for a mean of 52 months (24 to 132). No recurrences were seen in the irradiation group. Two patients in the non-irradiated group had a recurrence. There were no local complications attributable to the irradiation.

Discussion

Jaffe, Lichtenstein and Sutro\(^9\) regarded the synovium of the tendon sheath, bursa and joint as an anatomical unit in which giant-cell tumour of the tendon sheath, also called pigmented villonodular synovitis, may occur. Localised and diffuse forms of pigmented villonodular synovitis arise in joints while extra-articular forms occur in bursae.\(^3,4,10-13\) In lesions related to tendon sheaths, complete excision is often difficult due to spread into the neighbouring synovium.\(^8\) Careful complete excision is required in order to prevent recurrence. Jaffe\(^5\) recommended radiotherapy in a dosage of 15 to 25 Gy given in divided doses of 1.5 Gy daily when treating recurrences. This led us to investigate the role of postoperative radiotherapy as prophylaxis against recurrence. It was not necessary to give radiotherapy to all patients and we chose those in whom there was: a) possible incomplete excision; b) the presence of mitotic figures on histological examination; or c) involvement of bone.

Although mitosis may indicate an activity, there is no evidence to suggest that these lesions are malignant or prone to metastasis.\(^14\) Malignant forms have also been described and are distinct from synovial sarcomata.\(^15,16\)

In our study, the rate of recurrence was 4% which is lower than previously reported rates of 25% to
There was no recurrence in patients who had radiotherapy. Since they were considered to be a high-risk group for recurrence we suggest that there is a role for radiotherapy in preventing local recurrence. We conclude that meticulous excision of giant-cell tumours of tendon sheath reduces the incidence of recurrence, and that post-operative radiotherapy in these cases is not indicated. Radiotherapy may have a role in cases in which complete excision may not be possible.
