We studied 100 fresh human shoulders in cadavers (mean age 76 years), and the range of passive abduction (RPA) in 100 volunteers with normal shoulders and in 90 patients with instability of the joint, over a period of six years.

The anatomical and clinical findings showed that passive abduction occurs within the glenohumeral joint only, is controlled by the inferior glenohumeral ligament and has a constant value in 95% of both shoulders in normal subjects. In patients with instability, 85% showed an RPA of over 105° with 90° in the contralateral shoulder. In the remaining patients a strongly positive apprehension test suggested a diagnosis of instability.

An RPA of more than 105° is associated with lengthening and laxity of the inferior glenohumeral ligament.

Received 5 October 1999; Accepted after revision 3 May 2000

Patients and Methods

There were three parts to the study: 1) in cadavers; 2) in volunteers; and 3) in patients with instability of the shoulder after injury.

Study in cadavers. We obtained 100 fresh normal human shoulders, 68 from women and 32 from men, with a mean age of 76 years (61 to 82). The scapula was fixed on a rigid frame with its medial edge vertical and the blade lying at an angle of 30° anterior to the coronal plane to reproduce the normal position along the thorax. All the muscles of the GHJ were removed leaving the ligaments intact and the joint cavity closed.

The maximum range of movement in all planes was measured using a goniometer. The landmark used to check the position of the arm was a line from the posterior edge of the acromion to the lateral epicondyle. The structures responsible for limitation of movement were observed. Measurements were made in neutral rotation. The ranges of abduction and elevation were recorded before and after section of the IGHL.

Study in volunteers. There were 100 volunteers, 63 men and 37 women with a mean age of 28 years (24 to 38).

Clinical. In order to measure the range of passive abduction (RPA), the physician stood behind the patient with his...

forearm pushed down firmly on the shoulder girdle in its lowest position, while lifting the relaxed upper limb in abduction with his other hand. During the test, the elbow was flexed at 90° and the forearm was horizontal (Fig. 1). Under these circumstances the shoulder girdle should not move. Any movement was recorded with a goniometer. The measurements were made twice by the same operator and repeated by another.

This test was performed in healthy volunteers with normal shoulders and also in volunteers under anaesthesia just before a total hip or knee replacement. Coefficients of correlation between each series of measurements were calculated.

Radiological study. This was undertaken in 20 volunteers, 11 men and nine women with a mean age of 27 years (24 to 30). Radiographs were taken to confirm that the RPA was normal. The beam was horizontal, facing the GHJ and perpendicular to the coronal plane (Fig. 2). Radiographs were taken in two positions of the GHJ with the arm resting across the chest and in full passive abduction. The position of the clavicle was checked on the radiographs. The angle A between the axillary border of the scapula and the vertical line was measured. The projection (Rv) of the angle of rotation of the scapula within the coronal plane was obtained by subtracting the angle A measured at rest from that in passive abduction. The scapula rotates up to 5° during the test so that the measured range of passive abduction corresponds to the abduction within the GHJ.

Study in patients with instability of the shoulder. Patients with chronic instability of the shoulder after injury were studied for six years. Those with an associated multidirectional hypermobility were excluded leaving patients with a sulcus sign of inferior subluxation of less than 2 cm of the head of the humerus less than 70° of external rotation and a significant drawer sign. There were 56 men and 34 women with a mean age of 24.3 years (18 to 40), of whom 60 had recurrent dislocation and 30 transient instability. Measurements of passive abduction were recorded for both shoulders.

The test was also performed under anaesthesia before reconstructive surgery. The condition of the IGHL (torn or

continuous), the type of its insertion into the glenoid and the presence of a Bankart lesion were recorded.

A modified Bankart procedure was performed with sutures being inserted at three positions for the right shoulder, as shown in Figure 3. The position of the arm during insertion of the sutures is given in Table I.

The test was repeated at follow-up.

Results

Anatomical study in cadavers. The range of elevation was between 105° and 115° (Table II). In maximum elevation, the IGHL was symmetrically stretched so that the entire

Figure 6b – The detachment of the IGHL from the glenoid rim allows additional abduction (SS, subscapularis muscle; IGHL, inferior glenohumeral ligament).
ligament was responsible for the terminal restriction of elevation; this included the anterior band, the axillary pouch and the posterior band (Fig. 4). The mean abduction was 83.5° (80 to 85, SD 1.6). In maximum abduction, the IGHL was stretched asymmetrically and only its anterior part limited movement (Fig. 5). Neither the acromion nor the greater tuberosity limited movement. The range of elevation was not altered by section since the posterior part of the ligament, which was tense in maximum elevation, was left intact. Section of the posterior part of the ligament allowed a mean additional elevation of 12° (10 to 14).

Study in volunteers

Clinical. The results are presented in Table III. The mean RPA was 89.7° on the right and 89.8° on the left; 95% of subjects had between 85° and 90° of passive abduction and 5% more than 100°.

In 30 patients with normal shoulders both shoulders were tested under anaesthesia. The mean RPA was 88.6° (SD 3.5) on the right and 88.9° (SD 2.1) on the left side (chi-squared test, 0.99).

The coefficients of correlation (Table IV) for the measurements on the same side by the same operator were 0.87 (right) and 0.90 (left). Those for the measurements recorded by two operators on the same side were 0.84 (right) and 0.89 (left).

Radiological. The clavicle remained horizontal on all radiographs. The maximum Rv angle, which describes the rotation of the scapula in the coronal plane, was 5° (mean value 3°, SD 0.9), and the scapula therefore contributed less than 6% to the RPA (Fig. 7).

Study of patients with instability. In 85% of cases the RPA was more than 105°, as recorded by two physicians (Fig. 8), whereas the maximum on the contralateral side was 90°, except in two, in whom both shoulders were affected. The remaining patients experienced apprehension during the test with reflex muscle contraction; the recording of the RPA was therefore unreliable.

The measurements were repeated under anaesthesia before surgery. The RPA was more than 105° on the affected side in patients who had experienced apprehension, and less than 90° on the normal side.

The IGHL was recorded as being in continuity in all patients except two. In one there was a tear on the humeral side, and in the other a complete detachment of the capsule from the glenoid. Labral lesions of varying significance were found in each case. The most significant lesions of the labrum were found in patients with recurrent dislocation. Apart from one patient with a Broca-Hartmann pouch, the IGHL was always attached either directly to the rim of the glenoid or medially along the anterior aspect of the neck of the scapula for up to 6 mm at most.

At a mean follow-up of 15 months (8 to 36) the RPA was 90° in 89 of the 90 patients (Fig. 4). The patient with an RPA of more than 105° was the only early failure in the series, with a tear of the repair which required revision.

Discussion

There have been many descriptions of the anatomy and function of the IGHL. Some authors have emphasised that elevation and abduction are limited by contact of the greater tuberosity either beneath the acromion or with the upper margin of the glenoid. Our study confirms the function of the IGHL in limiting elevation and abduction of the GHJ. The small range of rotation of the scapula during the test demonstrates that passive abduction only occurs at the GHJ and is limited by the IGHL.

Clinically, inferior stability is assessed by the sulcus test or by the abduction inferior stability (ABIS) test described by Itoi et al., with the arm at 90° of abduction. Motzkin, Itoi and Morrey divided the anteroinferior half of the capsule and recorded significantly increased inferior translation of the humeral head. This suggests that the middle and inferior glenohumeral ligaments contribute to inferior stability with the arm in abduction and also that these ligaments limit abduction.

Of the volunteers 5% had an RPA of more than 100° in

both shoulders, suggesting increased laxity of the joint. Associated signs of generalised hypermobility were not recorded. There were no shoulders in the anatomical study with increased abduction, probably because of the advanced age of the patients (mean 76 years).

We were able to confirm that the range of elevation of the GHJ is more important than that of abduction, as has been reported previously.\(^\text{16,17}\) In full elevation, the IGHL is symmetrically tensed at its maximum length whereas in full abduction, the ligament is asymmetrical and thus shorter. It is therefore important to perform the test in the coronal plane.

In patients with chronic instability, the continuity of the IGHL found at surgery and the increase of the RPA seen under anaesthesia show a constant relation between instability and increased length of the IGHL. This confirms the finding of Bigliani et al\(^\text{18}\) and Urayama et al\(^\text{4}\) that, at the time of the first dislocation, the IGHL sustains permanent damage, and lengthens further with each dislocation. Speer et al\(^\text{19}\) showed that an experimental Bankart lesion alone did not induce instability. Before operation, the test showed lengthening of the IGHL in 85% of patients, and thus the measurement of passive abduction may be used as a test of the laxity of the IGHL (hyperabduction test). A positive hyperabduction test (\(> 105^\circ\)) indicates laxity of the IGHL; a negative test (\(85^\circ\) to \(90^\circ\)) indicates a normal IGHL.

In 15% of patients, however, passive abduction was limited by apprehension, which contributes to the diagnosis of instability.\(^\text{14}\)
